

SWCON104 Web & Python Programming

Boolean

Department of Software Convergence

Today

- Review the type str
- Type bool: A Boolean type
- Boolean operators: and, or, not
- Relational operators: >, <, >=, <=, ==, !=</p>
- Truth table
- Combining comparisons (precedence)
- Short-circuit evaluation
- Comparing strings

[Textbook]
Practical Programming
(An Introduction to Computer Science Using Python),
by Paul Gries, Jennifer Campbell, Jason Montojo.
The Pragmatic Bookshelf, 2017

Practice

Practice_06_Boolean.ipynb

String

- In Python, text is represented as a string.
- String is a type. (str)
- String is a sequence of characters.
- Characters include letters, digits, and symbols.
- Characters include Latin alphabet, 한글, chemical symbols, musical symbols, and much more.

How to define a string?

- Single quotes
- Double quotes

The opening and closing quotes must match.

```
>>> 'Aristotle'
'Aristotle'
>>> "Issac Newton"
'Issac Newton'
>>> 'Charles Darwin"
SyntaxError: EOL while scanning string literal
>>>
```

Empty string

- 69
- 6679
- It contains no character.
- It's not a blank. It's an empty string.
- How long can a string be?
 - Limited only by computer memory.

Operations on strings

- Python built-in functions for string
 - len(): returns the length of a string
 - +: concatenates two strings
 - *: repeats and concatenates strings
 - o int(): converts a string of numbers to integer type
 - float(): converts a string of numbers to floating-point type

print()

```
>>> a = 'one'
>>> a
'one'
>>> print(a)
one
>>> b = 'one\ntwo\nthree'
>>> b
'one₩ntwo₩nthree'
>>> print(b)
one
two
three
>>> c = 'one\ttwo\nthree\tfour'
>>> C
'one₩ttwo₩nthree₩tfour'
>>> print(c)
        two
one
three
        four
```

input()

```
>>> species = input()
Homo sapiens
>>> species
'Homo sapiens'
>>> population = input()
6973738433
>>> population
'6973738433'
>>> type(population)
<class 'str'>
>>> species = input("Please enter a species: ")
Please enter a species: Python curtus
>>> print(species)
Python curtus
```

```
>>> population = input()
6973738433
>>> population
'6973738433'
>>> population = int(population)
>>> population
6973738433
>>> population = population + 1
>>> population
6973738434
>>> population = int(input())
6973738433
>>> population = population + 1
6973738434
```

Making choices

- A Boolean type, bool can have the value either true or false.
- Boolean operators: and, or, not
 - onot is a unary operator: the operator is applied to just one value
 - and, or are binary operators: the operator is applied to two values.

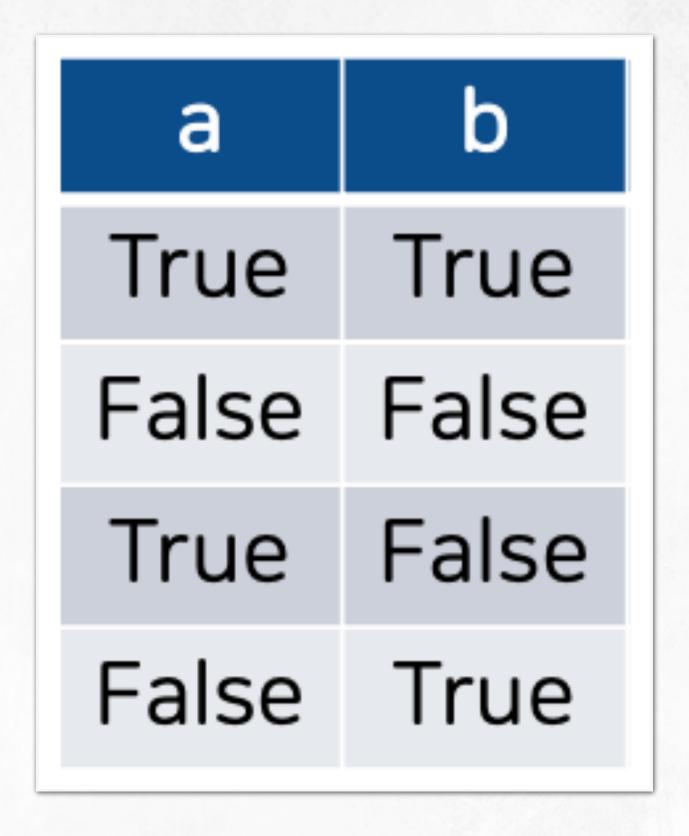

```
>>> not True
False
>>> not False
True
```

```
>>> True and True
True
>>> False and False
False
>>> True and False
False
>>> False and True
False
False
```

```
>>> True or True
True
>>> False or False
False
>>> True or False
True
>>> False or True
True
```

Truth table

When a and b are Boolean type variables,

- Inclusive or (OR) vs. Exclusive or (XOR)
 - Inclusive or: a or b (False if and only if both are False)
 - Exclusive or: Do you want to meet on Monday or Tuesday?
 - a XOR b is represented as (a and not b) or (not a and b)

Relational operators

>>> 45 > 34
True
>>> 45 > 79
False
>>> 45 < 79
True
>>> 45 < 34
False
>>> 23.1 >= 23
True
>>> 23.1 >= 23.1
True
>>> 23.1 <= 23.1
True
>>> 23.1 <= 23
False

>>> 67.3 == 87
False
>>> 67.3 == 67
False
>>> 67.0 == 67
True
>>> 67.0 != 67
False
>>> 67.0 != 23
True

Symbol	Operation
>	Greater than
<	Less than
>=	Greater than or equal to
<=	Less than or equal to
==	Equal to
!=	Not equal to
	elational and Equality Operator

How to use Booleans?

```
def is_positive(x):
    """
    (number) -> bool
    Return True iff x is positive.
    >>> is_positive(3)
    True
```

```
>>> is_positive(-4.6)
False
```

```
>>> is_positive(0.0)
False
```

```
RESTART: C:/Users/jiyoung/AppData/Local/Programs
/Python/Python35/Scripts/test04.py
>>> is_positive(3)
True
>>> is_positive(4.6)
True
>>> is_positive(-4.6)
False
>>> is_positive(0)
False
```

а	b	a != b (a XOR b)
True	True	False
False	False	False
True	False	True
False	True	True

return x > 0

Combining comparisons

>>> x = 2	>>> x = 3
>>> y = 5	>>> 1 < x <= 5
>>> z = 7	True
>>> x < y and y < z	>>> 3 < 5 != True
True	True
>>> (x < y) and (y < z)	>>> 3 < 5 != False
True	True
>>> (1 < x) and (x <= 5)	>>> (3 < 5) and (5 != True)
True	True
>>> (1 < z) and (z <= 5)	>>> (3 < 5) and (5 != False)
False	True

Numbers and Strings with Booleans

- Numbers
 - O and 0.0 are treated as False
 - All other numbers are True

- Strings
 - Empty string is treated as False
 - All other strings are True

```
>>> not ''
True
>>> not ""

>>> not ""
True
>>> not 'bad'
False
```

None is treated as False

Short-circuit Evaluation

- When Python evaluates an expression containing or, if the first operand is True, Python doesn't evaluate the second operand.
- When Python evaluates an expression containing and, if the first operand is False, Python doesn't evaluate the second operand.

```
>>> 1/0
Traceback (most recent call last):
   File "<pyshell#34>", line 1, in <module>
        1/0
ZeroDivisionError: division by zero
>>> (2<3) or (1/0)
True</pre>
```

Comparing strings

ASCII: American Standard Code for Information Interchange

```

```

Comparing strings

- Lexicographically
- Checks whether one string appears inside another one
- Case sensitive
- Empty string is always a substring of every string

```
>>> 'A' < 'a'
                       >>> 'Jan' in '01 Jan 1838'
                       True
True
>>> 'A' > 'z'
                       >>> 'Feb' in '01 Jan 1838'
                       False
False
>>> 'abc' < 'abd'
                       >>> date = input('Enter a date in the format DD MTH YYYY: ')
                       Enter a date in the format DD MTH YYYY: 20 Mar 2017
True
>>> 'abc' < 'abcd'
                       >>> 'Jan' in date
True
                       False
>>> '가' < '나'
                       >>> 'Mar' in date
                       True
True
                       >>> 'a' in 'abc'
>>> '가나' < '가다'
                       True
True
                       >>> 'A' in 'abc'
>>> '가나다' < '가나'
                       False
False
>>> '가' > '거'
                       >>> "" in 'abc'
False
                       True
```

Summary

- Python uses Boolean values, True and False, to represent what is true and what isn't. Programs can combine these values using three operators: not, and, and or.
- Boolean operators can also be applied to numeric values. 0, 0.0, the empty string, and None are treated as False; all other numeric values and strings are treated as True. It is best to avoid applying Boolean operators to non-Boolean values.
- Relational operators such as "equals" and "less than" compare values and produce a Boolean result.
- When different operators are combined in an expression, the order of precedence from highest to lowest is arithmetic, relational, and then Boolean.

Thank you
